Blast Wave from a Spherical Charge

HAROLD L. BRODE
The RAND Corporation, Santa Monica, California
(Received July 10, 1958; revised manuscript received December 10, 1958)

The blast wave from the detonation of a spherical charge of TNT is described based on results of a numerical calculation. The equations of motion and the equations of state for TNT and for air are described. The pressures, densities, temperatures, and velocities are detailed as functions of time and radius. Space-time relations and energy and impulse histories are shown. A second shock is seen to originate as an imploding shock following the inward rarefaction into the explosion product gases and a series of subsequent minor shocks are seen to appear in a similar manner, moving out in the negative phase behind the main shock.

I. INTRODUCTION

IN the considerable study devoted to high-explosive detonations and their resulting blast waves, much use has been made of experimental information. (The first three references[1-3] are examples of the exhaustive analyses possible from such data.) With the more powerful computational aids now available, it is possible to develop solutions to detonation problems without reliance on empirical values derived from explosion measurements. One such solution is reported on here. The hydrodynamical equations of motion, which constitute a set of nonlinear partial differential equations, were integrated by a numerical procedure on a high-speed electronic computer. The propagation of shock discontinuities was handled by a common form of the artificial viscosity technique of von Neumann and Richtmyer,[4] as used in earlier work.[5]

The initial conditions for this particular blast calculation were approximately those of the centered detonation of a bare sphere of TNT of loading density 1.5 g/cm^3 as specified by the detonation wave descriptions of Taylor.[6] The equation of state of this TNT was modeled after that of Jones and Miller,[7] and the equation of state of air was a fit to computed data of several authors but primarily that of Gilmore[8] and of Hilsenrath and Beckett.[9]

The results show clearly the details of the main shock in air, the rarefaction into the high-explosive gases, the second shock (one which follows the rarefaction wave), and various subsequent reflections and refractions of the second shock between the origin and the contact surface. Comparison with the results of a massless point-source explosion illustrates the lasting effects on the blast wave of the initial mass and energy distribution of a high-explosive detonation.

II. EQUATIONS OF MOTION

The equations of motion may be expressed in a Lagrangian form with the independent variables being the time (t) and a mass coordinate (X) where X is defined as $X = \rho_1 r_0^3/3$ (i.e., the mass per steradian) for which ρ_1 is the initial density of the gas and r_0 its initial radius. The hydrodynamic equations for spherical symmetry may then be written as follows:

$$\frac{1}{\rho} = R^2 \frac{\partial R}{\partial X}, \quad \text{conservation of mass;} \tag{1}$$

$$\frac{\partial u}{\partial t} = -R^2 \frac{\partial P}{\partial X}, \quad \text{conservation of momentum;} \tag{2}$$

$$\frac{\partial E}{\partial t} = \frac{P}{\rho^2} \frac{\partial \rho}{\partial t}, \quad \text{conservation of energy;} \tag{3}$$

$$P(E, \rho), \quad \text{caloric equation of state;} \tag{4}$$

$$T(E, \rho), \quad \text{thermal equation of state;} \tag{5}$$

$$u = \frac{\partial R}{\partial t}, \qquad \text{definition of particle velocity;} \quad (6)$$

in which ρ is the density, R is the radial position, u is the particle velocity, P is the pressure, E is the internal energy, and T is the temperature.

It is convenient to reduce these equations to a dimensionless set which then may be applied to any initial total energy (w) and any initial preshock conditions (P_0, ρ_0, T_0, E_0), where these ambient units are related as follows:

$$\alpha^3 = w/P_0, \quad (7)$$

$$E_0 = P_0/\rho_0(\gamma_0 - 1), \quad (8)$$

or

$$P_0/\rho_0 E_0 = (\gamma_0 - 1) = 0.4,$$

$$C_0^2 = \gamma_0 P_0/\rho_0, \quad \text{or} \quad C_0^2 \rho_0/P_0 = \gamma_0 = 1.4. \quad (9)$$

Upon defining the following reduced variables,

$$\pi = P/P_0, \quad \text{(pressure in atmos);}$$

$$\eta = \rho/\rho_0, \quad \text{(relative density);}$$

$$\beta = u/C_0, \quad \text{(particle Mach number);}$$

$$\epsilon = E/E_0, \quad \text{(internal energy);} \quad (10)$$

$$\theta = T/T_0, \quad \text{(temperature—}T_0\text{ in degrees absolute);}$$

$$\lambda = R/\alpha, \quad \text{(reduced radius);}$$

$$x = X/\rho_0\alpha^3 = \tfrac{1}{3}\eta_1\lambda_0^3 = \tfrac{1}{3}\rho_1 r_0^3/\rho_0\alpha^3, \quad \text{(mass units);}$$

$$\lambda_0 = r_0/\alpha;$$

$$\tau = tC_0/\alpha, \quad \text{(reduced time),}$$

the equations of motion become

$$\frac{1}{\eta} = \lambda^2 \frac{\partial \lambda}{\partial x} = \frac{1}{3}\frac{\partial \lambda^3}{\partial x}, \quad (11)$$

$$\frac{\partial \beta}{\partial \tau} = \frac{-1}{\gamma_0}\lambda^2 \frac{\partial \pi}{\partial x}, \quad (12)$$

$$\frac{\partial \epsilon}{\partial \tau} = (\gamma_0 - 1)\frac{\pi}{\eta^2}\frac{\partial \eta}{\partial \tau}, \quad (13)$$

$$\frac{\partial \lambda}{\partial \tau} = \beta. \quad (14)$$

It will be convenient to write the equations of state in still another form.

$$\theta = zS(z, \eta), \quad \text{where} \quad z = \pi/\eta, \quad (15)$$

and

$$\epsilon = (\gamma_0 - 1)(\mu - 1)z/2; \quad \mu(z, \xi), \quad \xi = \ln \eta. \quad (16)$$

Use of this expression [Eq. (16)] for ϵ in Eq. (13) leads to the following form of the energy equation:

$$\frac{\partial z}{\partial \tau} = \frac{[2 - (\partial\mu/\partial\xi)]z}{[\mu - 1 + z(\partial\mu/\partial z)]}\frac{\partial \xi}{\partial \tau}. \quad (17)$$

In order to integrate these equations numerically from some set of initial conditions, these equations must be replaced by an appropriate set of difference equations. Details of the difference equations and of the numerical procedure followed in solving them are available elsewhere[10] and so will not be repeated here.

III. EQUATIONS OF STATE

The two functions $S(z, \eta)$ and $\mu(z, \xi)$ which are determined ordinarily by equation-of-state data are not entirely independent. A reciprocity relation exists which places a constraint on these functions in order that they satisfy the second law of thermodynamics. For purely hydrodynamical considerations, however, there is no need to observe this restraint since the thermal equation is superfluous to the equation of motion. In such cases where the temperature is coupled to the hydrodynamics, e.g., as by radiation, heat conduction, or heat diffusion, it should be necessary to observe the reciprocity restriction. The analytic forms introduced in the following are intended to make such a constraint less difficult to comply with in fitting the two equations of state.

On choosing as our independent variables $z = \pi/\eta$, and $\xi = \ln \eta$, the second law in the form

$$ds = \frac{Dq}{T} = \frac{dE + p\,dv}{T}, \quad \text{where} \quad v = \frac{1}{\rho}, \quad (18)$$

becomes

$$\begin{aligned} \frac{\rho_0 T_0}{P_0} ds = \frac{1}{2S(z, \xi)} &\left\{\left(\frac{\partial \mu}{\partial \xi}\right)_z d\xi \right. \\ &\left. + \left[\left(\frac{\partial \mu}{\partial z}\right)_\xi + \frac{\mu - 1}{z}\right] dz\right\} \\ - \frac{d\xi}{S} &= \left[\frac{1}{2S}\left(\frac{\partial \mu}{\partial \xi}\right)_z - \frac{1}{S}\right] d\xi \\ &+ \frac{1}{2S}\left[\left(\frac{\partial \mu}{\partial z}\right)_\xi + \frac{\mu - 1}{z}\right] dz, \end{aligned} \quad (19)$$

and in order that ds be a perfect differential, the following reciprocity relation must hold:

$$\frac{\partial}{\partial z}\left[\frac{1}{2S}\left(\frac{\partial \mu}{\partial \xi}\right)_z - \frac{1}{S}\right] = \frac{\partial}{\partial \xi}\left[\frac{1}{2S}\left(\frac{\partial \mu}{\partial z}\right)_\xi + \frac{\mu - 1}{2zS}\right]. \quad (20)$$

To within 10% in the density range of interest the function S can represent the thermal properties

[10] H. L. Brode, "Point source explosion in air," The RAND Corporation, Research Memorandum RM-1824, December 3, 1956.

21 December 2023 05:53:12

of air as a function of z alone (independent of ξ). Furthermore, the function μ can fit the caloric properties to the same accuracy with the form

$$\mu = \mu_0(z) + \mu_1(z)\xi. \tag{21}$$

In this case, then, the reciprocity relation requires that

$$\mu_1(z) = 2zS'/(s + zS'). \tag{22}$$

The equation of state of air data was taken from earlier works of others,[11,12] and were subsequently revised to the later information of references 8 and 9. The fits used are as follows:

$$\begin{aligned} T/T_0 &= \theta = zS(z), \\ S(z) &= \frac{485}{0.1000 + z^2} + \frac{3860z}{7500 + 16.5z}, \end{aligned} \tag{23}$$

$$\begin{aligned} E/E_0 &= \epsilon = (\gamma_0 - 1)z(\mu - 1)/2, \\ \mu &= \mu_0 + 0.09(\mu_0 - \mu_2)\xi, \\ \mu_2 &= (6002y + 4)/(1000y + 1), \end{aligned} \tag{24}$$

where $y = z^{-1}$ and

$$\mu_0 = 1 + \frac{25.89486848y + 3}{4.778973696y + 1} + \frac{861(1 - y)y}{3000y^2 + 1} + \frac{2356(1 - y)y}{9 \times 10^4 y^2 + 1} + \frac{41\,000(1 - y)y}{12 \times 10^6 y^2 + 1}.$$

Equation of State of TNT

It is necessary that the detonation products have an internal energy plus kinetic energy equal to the net energy released by chemical reaction. Jones and Miller[7] indicate a net energy release of 247.9 kcal/mole of TNT (at 1.5 g/cc loading density) after the gas products have expanded to more than three times their initial volume and the temperature has dropped below 1600°K (for this loading density).

At the detonation front the chemical energy release is 288.6 kcal/mole of TNT. Part of this energy goes into the forming of such gases as carbon monoxide which increases rapidly behind the front.

The molar volume at the detonation front is given by Jones and Miller as 117 cm^3 and the density is 2 g/cm^3, so that the molecular weight is 234 g.

The internal energy is given approximately (by Jones and Miller) as

$$E = 0.0875T - 38.0 + N'E_1 \text{ kcal/mole} \cdots, \tag{25}$$

where T is in degrees Kelvin, and N' is the number of moles of gas per mole of TNT, a number that goes from 5.8 at the detonation front to 7.0 when the composition becomes fixed. E_1 is given as

$$E_1 = -\tfrac{1}{2}cp^2 - \tfrac{2}{3}dp^3 \text{ 1000 kg cm/mole} \cdots, \tag{26}$$

where $c = -0.104$, $d = 2.33 \times 10^{-4}$, and p is in 1000 kg/cm^2. By writing E_1 in kcal/mole TNT and p in atmos ($p/p_0 = \pi$), E_1 becomes

$$E_1 = (0.0234)[5.564 \times 10^{-8}\pi^2 - 1.72 \times 10^{-13}\pi^3] \text{ kcal/mole} \cdots. \tag{27}$$

Then E is

$$E = 0.0875T - 38.0 + N'(0.0234)(5.564 \times 10^{-8}\pi^2 - 1.72 \times 10^{-13}\pi^3) \text{ kcal/mole}. \tag{28}$$

At the detonation front where $T = 3400$°K, $\pi = 15.665 \times 10^4$ atmos, and $N' = 5.8$ the energy equals 355.07 kcal/mole TNT according to this expression. Even without the $N'E_1$ term it gives 259.5 kcal/mole TNT in contrast to the stated 288.6 kcal/mole TNT. Furthermore this form gives negative energies below 430°K.

For the sake of hydrodynamic calculation it is important to have the correct total energy. It is also desirable, but less important for later stages, to have its distribution approximately correct initially. It would be convenient to have the internal energy compatible with the ideal gas behavior of the mixture near standard atmosphere conditions. This latter consideration is satisfied by an energy that near standard conditions approaches the ideal gas expression,

$$E = p/\rho(\gamma - 1), \tag{29}$$

where γ is the same as the adiabatic γ which in this case is $\gamma = 1.27$. This is approximately satisfied by allowing E to go to $1.5\ E_0 = 2.94 \times 10^9$ ergs/g at standard conditions.

One can assure the correctness of the total energy by adding up the internal and kinetic energies in the hydrodynamic field at a time when the composition has become fixed.

If one were to start a blast calculation from a detonation wave at the instant the detonation wave reaches the surface of a spherical charge of TNT, then he would find that none of the resulting gas has reached a fixed composition. In that case the total energy in the field should lie somewhere between the chemical energy available at the detonation front and the net chemical energy released when composition becomes fixed, i.e., between 288.6 and 247.9 kcal/mole TNT.

21 December 2023 05:53:12

Upon using the equation of state as given [Eq. (28)] and the conditions behind the detonation front as specified by Taylor[6] (Table II, reference 6) and averaging over the mass distribution of the spherical charge, the total energy per mole of TNT can be computed.

$$E_{\text{tot}} = E_{\text{kinetic}} + E_{\text{internal}} = E_k + E_i, \tag{30}$$

$$E_i = 4\pi R^3 \int_0^1 E\rho y^2\, dy / 4\pi R^3 \int_0^1 \rho y^2\, dy = 209.8 \text{ kcal/mole}, \tag{31}$$

where $y = r/R$,

$$E_k = \int_0^1 \tfrac{1}{2}\rho u^2 y^2\, dy \Big/ \int_0^1 \rho y^2\, dy = 11.90 \text{ kcal/mole}, \tag{32}$$

$$E_{\text{tot}} = 221.7 \text{ kcal/mole}. \tag{33}$$

This latter total energy is less than the net energy released and so would seem to be incorrect, or at least undesirable.

By arbitrarily increasing the additive term in E, so that E becomes

$$E = 0.0875T - 7.46 + N'E_1 \text{ kcal/mole TNT}, \tag{34}$$

the figure for E_{tot} would become 252.28 kcal/mole TNT and at the same time the energy at standard temperature (273.2°K) becomes 16.44 kcal/mole TNT which is $1.5E_0$, as desired. On the other hand, this will raise the energy released at the detonation front by a corresponding amount, where we have already seen this figure to be too high by the previous form for E [Eq. (28)]. Since an incorrect total energy would seem to have a more lasting effect than an incorrect initial distribution, we were inclined to accept this arbitrary alteration and compute accordingly.

The excessively high energies near the detonation front could be reduced by lowering the pressure or raising the density there, and correspondingly, but to a lesser extent, at points behind the front. Such empirical adjustments of parameters are distasteful at best and always need to be done with care so that energies and densities remain in their proper proportions. This particular equation of state is itself an empirical relation intended only to approximate the effects of close packing on the gas molecules through the higher order pressure terms (where no temperature dependence has been assigned to the coefficients of these pressure terms). Consequently, we have elected to leave the pressures and densities, as described by Taylor,[6] unchanged, and to alter the internal energy by the constant factor [as in Eq. (34)]. This results in approximately the correct average energy per mole of TNT in the detonation wave and leads to a simple form for conditions near standard air density and temperature. It does, however, lead to a spurious signal of little consequence in the early portion of the explosion.

By using the equation of state from Jones and Miller as modified in Eq. (34), and dividing by the internal energy of air at standard conditions ($E_0 = 1.96 \times 10^9$ ergs/g), one finds that the internal energy is

$$\begin{aligned} \epsilon &= (a\theta - b + c\pi^2 N' - d\pi^3 N')/5 \\ &= (azS(z) - b + cz^2\eta^2 N' - dz^3\eta^3 N')/5. \end{aligned} \tag{35}$$

Also, by definition, μ and ϵ are related as

$$\mu = \frac{\gamma+1}{\gamma-1} = 1 + \frac{5\epsilon}{z} = 1 + aS - \frac{b}{z} + cz\eta^2 N' - dz^2\eta^3 N', \tag{36}$$

$$z\mu_z = aS'z + \frac{b}{z} + c\eta^2 N'z - 2\, dz^2\eta^3 N'. \tag{37}$$

These expressions are a little cumbersome, so the form of μ along the particular adiabat followed by much of the HE (high explosive) was simply fit by the analytical form,

$$\mu_{\text{HE}} \simeq = 1 + a + bz/(c + z^2), \tag{38}$$

in which $a = 1.76$, $b = 52.4892$, $c = 7.300$. This simpler form was incorporated in the calculations with the understanding that it is valid only for a particular loading density of TNT ($\rho_{\text{HE}} = 1.5$ g/cc). The former, more general form should be applicable for a variety of densities. However, Jones and Miller do not state that their approximate form for the internal energy is valid for explosives other than TNT.

The approximate temperature (θ), in units of standard air temperature ($T_0 = 273.2$°K), may be computed for the TNT gases by the form

$$\theta = zS(z), \qquad S = 12/(9.65 + z), \tag{39}$$

in the range of z between detonation temperatures and ambient air temperatures.

IV. INITIAL CONDITIONS AND SCALING

The conditions in the detonation wave at the instant that the front reaches the surface of the bare spherical charge of TNT were taken to be those prescribed by Taylor as shown in reference 6, Table II. The conditions in the air surrounding the charge

21 December 2023 05:53:12

were taken as standard sea level air conditions: $P_0 = 1.01375 \times 10^6$ dynes/cm^2, $\rho_0 = 1.293 \times 10^{-3}$ g/cm^3, $c_0 = 33{,}136$ cm/sec, $T_0 = 273.2°$K.

The units of the problem permit easy scaling to other atmospheres and to any energy or charge size, but since the initial conditions for the high explosive are expressed in the same units, any one solution can only be scaled to other atmospheric conditions with an accompanying and proportional change in the explosive and detonation wave conditions. This is an unavoidable limitation since in any chemical explosive detonation the blast wave will be influenced by the initial mass out to very-low-pressure levels—until such shock radii as would engulf a mass of air roughly ten times the mass of the explosive. For a sphere of TNT at sea level this would mean roughly 23 charge radii, or out to an overpressure of five atmospheres or about 70 psi. As will be seen in the next section (Fig. 1), this distance is about the distance where the overpressure decay rate becomes that of the point-source blast wave. In the thinner atmosphere at 40 000-ft altitude, for example, the corresponding distance where the shock has engulfed a mass of air ten times that of the explosive is more like 36 charge radii, and the overpressure there is a maximum of 17 psi. As a result of this mass effect, only at distances greater than the radius at which a mass of air of ten times the initial mass has been engulfed, is it reasonable to scale these results by the usual (Sach's) scaling. At points nearer to the explosion the effect of the initial mass should prevent simple scaling.

When the explosive loading density is scaled by the same factor as the ambient air density the results of this calculation should again be applicable. As at 40 000 ft, the scaled results should be appropriate to a TNT sphere of loading density of 0.375 g/cm^3 if such an explosive could exist.

V. RESULTS

The peak overpressure as a function of shock radius is shown in Fig. 1. It is interesting to note the comparison with the theoretical point source results for air[10] and for an ideal gas of $\gamma = 1.4$.[5] Although at no stage are the TNT and point-source in air results the same, their slopes at large distances ($\lambda > 1$) become similar. The ideal gas, point-source curve shows higher pressures at the same distances, since the various dissociations and ionizations of molecules and atoms in high-temperature air near the source tend to reduce the blast efficiency in real air. Since the TNT source does not shock air to extreme temperatures ($T < 9000°$K) its later profiles

FIG. 1. Peak overpressure ($\Delta p_s = \pi_s - 1$) in atmospheres *versus* shock radius ($\lambda_s = R_s/\alpha$, $\alpha^3 = W_{tot}/p_0$) with comparisons between TNT and point-source blasts in both real air and an ideal gas ($\gamma = 1.4$). The dash-double-dot curve is from the results of Wecken for 50% RDX – 50% TNT (reference 2). The short dotted curve is from the Berry, Butler, and Holt calculations for PENT (reference 13).

indicate a greater blast efficiency than the point source in air.

The peak overpressure as reported by Schardin[2] from Wecken's calculation is shown as the dotted curve of Fig. 1, and indicates a higher initial pressure with a similar early decay. Wecken's explosive was of somewhat greater energy density (50% RDX–50% TNT), which would account for the higher initial overpressure in the air shock. The more rapid decay at later times is possibly due to the use of an ideal gas for air. The use of an ideal gas law for the explosion product gases may also influence the early portion of the curve.

The open-dot curve represents the results of a numerical integration by Berry, Butler, and Holt[13] for a similar explosion, but again using an ideal gas for the explosive products ($\gamma = 3$) and for air ($\gamma = 1.2$), and also assuming the air shock to be a "strong shock." In this latter case, the initial or detonation conditions assumed include velocities and pressures even higher than those of Wecken's explosion. In both cases, the agreement seems reasonable in view of the differences in initial con-

The dashed curves are from Wecken's calculation, showing the main and second shocks and portions of the contact surface and third shock. The present calculation was carried to later times and larger distances than shown.

shock radius does seem to suffer from the strong shock assumption.

Granstrom has prepared a peak overpressure-distance curve for TNT of loading density 1.52 g/cm^3 which he estimates to be valid to within 5%, and which he states is in agreement with the most reliable observations.[3] His curve (Fig. 25 of reference 3) lies above the curve for TNT in Fig. 1 by about 5% in radius out to a λ of about 1.0, beyond which it deviates slightly more. This is a rather modest discrepancy but it nevertheless means an average blast energy efficiency of some of 16 or 17% greater for the Granstrom curve.

The deviation in the last portion of the pressure curve ($\lambda > 1.0$) is attributable to inexact treatments in the numerical procedure used for doubling and adding zones during the late stages of the calculation.

Figure 2 is a plot of the peak mass velocity or the particle Mach number ($\beta_s = u_s/C_0$) at the shock and the shock overvelocity or shock Mach number in excess of Mach one [$B - 1 = (U - C_0)/C_0$] *versus* shock radius for the main shock. Figure 2 also includes a similar plot of the shock compression [$\eta_s - 1 = (\rho_s/\rho_0) - 1$] and the shock overtemperature [$(T_s/T_0) - 1 = \theta_s - 1$] *versus* shock radius.

The positions of the main and subsequent shocks as well as the contact surface as functions of time are indicated in Fig. 3. The second shock follows a rarefaction wave into the TNT gases. It starts with zero strength and grows as it moves inward through these gases. It is swept outward in space until the expansion of the high-explosive products is nearly exhausted; then it implodes on the origin and is reflected outward to the contact surface. At the time it strikes the contact surface between the TNT gases and the air, the TNT gases are still more dense and much cooler than the air immediately outside, (a condition which is generally true at any time). As a consequence, the shock in passing through the surface sets up an inward rarefaction wave. This rarefaction, like the initial rarefaction, is followed by a third shock moving inward. This shock, like the second, implodes on the origin, reflects, and moves out in the wake of the previous shocks. The succession of shocks continues in this fashion until the energy in the explosion product gases is dissipated.

The origin of these inward facing shocks lies in the necessity for a compression wave at the juncture of a spherical rarefaction wave moving away from a spherical shock wave. No such condition exists in a plane shock tube; however, in general (not just in detonations), a spherical shock wave from a source of finite volume is backed up to a rarefaction wave moving inward, and the negative pressure gradient of the rarefaction joins the positive gradient of the

FIG. 4. Division of blast energy between kinetic (Q) and internal (E) as a function of time for a TNT blast ($E + Q = 1$).

FIG. 5. Particle velocity ($\beta = u/c_0$) *versus* radius ($\lambda = r/\alpha$) at indicated times for a TNT blast. The dashed curves are from Wecken's work.

shock through a compression which grows as a shock as the rarefaction develops.[14]

These subsidiary shocks follow the main shock at such a time and distance that they are behind the minimum of the negative phase and do not converge on or join the main shock. For a hotter gas explosion, where these shocks would move out earlier, it is possible for them to overtake and join the main shock and so disappear.

The dashed curves in Fig. 3 approximate Wecken's results, and indicate a foreshortening of the time scale which might be expected from his use of ideal gas laws leading to relatively high sound speeds in both explosion products and air. Otherwise, the general features appear quite similar. The rather deep retraction of the contact surface (in Wecken's case) following the inward shock may also be a result of the simple equation of state assumptions.

The energy in the detonation wave is distributed as 95% in internal energy or potential (pv) energy and 5% in kinetic energy of directed motion. As the rarefaction into the dense HE gases develops, the dynamic motion or kinetic energy increases, reaching a maximum of better than 60% before dissipation in the shock heating reduces it again to a low value. This changing division of energy between kinetic and internal is illustrated in Fig. 4, which shows the partition of energy as a function of time.

Figures 5 through 8 show the history of the particle velocities as a function of radius. The time is considered to be zero at the instant that the detonation wave reaches the surface of the TNT sphere. The velocities in the detonation wave (time zero) and at a few times immediately after time zero are shown in Fig. 5. Early evidence of the second shock appears just inside the contact surface as a small jump in velocity. This second shock can be seen to grow in magnitude and to recede inward from the contact surface (Figs. 5 and 6). At approximately $\tau = 0.136$ the second shock reaches the origin and is reflected, so that in Fig. 6 it is shown moving outward. The dashed curves, labeled W, are from Wecken's calculation. It is rather curious that, after reflection on the origin, his second shock does not turn the flow outward, but leaves the gas still compressing toward the center after passing (see Fig. 6, $\tau = 0.1260 - W$).

A rather complicated series of shock reflections and refractions can be traced out in Fig. 7, resulting in the generation of a third and fourth shock. The earliest curve in Fig. 7 shows the second shock just after having breached the contact surface. The next curve shows a third shock moving inward, and the subsequent curves picture this third shock moving out behind the second and first shocks, generating a fourth shock in the process.

In the last velocity plot (Fig. 8) these first four shocks can be seen to continue expanding. Because of the difficulty in distinguishing further shocks, no attempt was made to indicate any more than these first four shocks.

Pressures as a function of radius at selected times are shown in Figs. 9 through 12. In the first of these, Fig. 9, the first shock can be seen to start at about 400 atmos, far below the 200 000 atmos of the

detonation wave. Immediately behind the contact surface the second shock appears and grows in strength as it is forced outward by the expansion. After the rarefaction has reduced the high interior pressures to less than one-tenth of an atmosphere this second shock begins to move in on the origin. Until this shock reaches the origin the pressure inside continues to drop because of the continuing rarefaction, reaching something less than 0.08 atmos before being hit by the second shock. Figure 10 shows pressure profiles before and after the implosion of this inward shock.

Figure 11 shows more of the complications due to the creation of repeated little shocks. Again no attempt is made to indicate shocks after the fourth one, although there is reason to believe that such

subsidiary shocks continue to form in a similar manner.

The early history of the density profiles is told by Figs. 13 and 14. The initial density of the high explosive is slightly altered by the passage of the detonation wave, but having an initial density in this problem of 1.5 g/cc, the TNT density at the start of the calculation is more than a thousand times the standard density of air. As the TNT gases expand their density is rapidly decreased. As an air shock builds up outside the surface of the TNT gases, the second shock begins to grow and move inward behind the contact surface (see Fig. 13). This results in a density profile at these times which is characterized (as one moves inward from the shock front) first, by a decrease in density in the air due to the spherical expansion, second by the density discontinuity at the contact surface which is shown by the sudden jump to higher density in the high-explosive products, and thirdly by the inward facing second shock which, although moving in through the

mass of TNT gases, is being swept out by the general rarefaction.

At later times the explosion products and some of the surrounding air are left at rest but at a relatively low density compared to normal air density. This hot, low-density region extends out to a radius of about $\lambda \simeq 0.5$, but in reality would not persist, as radiation and convection would cause this bubble to cool and shrink.

Figure 15 shows some of the early temperature profiles where again the existence of the contact surface and the second shock somewhat complicate the picture. It should be noted that temperatures exceed 2000° Kelvin for a time, rising as high as

8000 or 9000° in the air at the earliest times. Some radiation should be visible from this hot air during this time, but not enough energy can be lost by radiative processes to affect the hydrodynamics. The TNT gases do not exceed 3000° in the detonation process and rapidly cool below that temperature in the expansion phase, but unlike the air, these gases may radiate effectively below 2000° and so may give off more light.

Figures 16 and 17 show pressures as functions of the time at selected radii. Figure 16 is a log-log plot of the pressure (in atmospheres) *versus* the time, showing the complicated time behavior of pressures at distances close enough to be engulfed by the explosion products. Such points are at radii out to as much as ten times the charge radius. At these distances the second shock first backs through the point, then comes back in past that point, and after imploding finally comes out again. The third and fourth shocks can also be seen going in and coming out again, since by then these radii all lie inside the contact surface. Figure 17 shows the more conventional overpressure-time histories in which the main shock is followed by a negative overpressure phase on the back of which the second, third, and subsequent shocks appear.

The durations of positive phases of overpressure and velocity are shown in Fig. 18 along with the positive impulses for the overpressure and for the dynamic pressure as function of the air-shock overpressure. These impulses are defined as follows:

$$I_p^+ = \int_{\tau_s}^{\tau_s + D_p^+} \Delta p \, dt, \quad \text{and} \quad I_u^+ = \int_{\tau_s}^{\tau_s + D_u^+} \frac{\gamma \eta \beta^2}{2} \, dt.$$

It is interesting to note that the dip in overpressure

impulse occurs at the same time that the internal energy goes through a minimum and the kinetic energy reaches a maximum. Furthermore, the region of the dip in the overpressure impulse is one which is engulfed both by the TNT explosion product gases and by the second shock while it is being dragged backwards by the rarefaction. In a sense, the dip is artificial, and arises in the influence of the second shock which in this region serves as a premature end to the positive phase.

VI. CONCLUSIONS

The present calculation stands as only one of many examples of the degree of detail and accuracy that is possible in following the development of a hydrodynamics problem, in particular, one involving shocks by means of the von Neumann-Richtmyer artificial viscosity technique. The method offers a number of attractive features: (1) No limiting physical assumptions need be imposed on the differential equations to reduce them to ordinary equations or to make them more simply integrable—rather one deals with the partial differential equations sans similarity restrictions. (2) Shock waves are handled automatically, and no special computational technique is required if the problem contains multiple shocks or when shocks impinge on the origin, i.e., there are no floating boundary conditions to be satisfied separately. (3) The complexity of the computations is not seriously increased by allowing for the computation of detailed equations of state from either tabular data or from analytic fits. (4) The method is adaptable to large ranges in time and space variables, i.e., expansions around singular points are nowhere necessary. Although the present results are not addressed to the questions involved in the initial growth of the second shock, the technique is most appropriately applicable and is capable of a high degree of accuracy without the many laborious algebraic transformations and limiting physical assumptions.[15–17]

As comparison with the excellent work of Wecken indicates, the assumptions about equations of state

of the high explosive and of air do influence the blast wave strength and structure. The influence, however, is not as great as might be predicted on purely thermodynamic grounds, since in these dynamic shock problems pressures and velocities tend to be less sensitive to equation-of-state variations than are temperatures and densities. In the strong-shock, high-temperature regions, the effect of nonideal gas properties is almost always appreciable, and the importance persists to late times, as the difference between peak overpressures for the point source solutions in ideal gas ($\gamma = 1.4$) and in real air indicates (Fig. 1). Holt[17] concludes on comparison with the results of his earlier work with Berry[16] that the equation of state for high explosive is of importance in even the early development of the second shock. His results, unfortunately, are not extendible beyond the earliest times after detonation.
